Insect and mite pests of honeylocust

Whitney Cranshaw

Several insects and mites are commonly found on honeylocust trees in Colorado. However, they rarely affect the health of the tree.

Honeylocust podgall midge deforms new leaves of honeylocust in late spring. One to two insecticide applications started at the occurrence of first new growth can limit this injury, if necessary.

Plant bugs also feed on new growth and compete with pod gall midge.

Late season build-up of spider mites are common on honeylocust. Water sprays, insecticidal soaps and certain miticides can limit this injury.

Several insects and mites feed on honeylocust trees in Colorado. Their feeding can cause conspicuous injuries that may make the trees unattractive. Heavy infestations can reduce tree growth rate and vigor and cause some twig dieback. However, it is extremely rare that these injuries alone permanently injure the trees. Plant diseases, notably Thryonecsta and Tubercularia cankers (Service in Action sheet 2.939, Cankers of honeylocust), are far more important to the health of honeylocust.

Honeylocust Podgall Midge

The immature stages (larvae) of a small fly, the honeylocust podgall midge, commonly cause distortions of new honeylocust growth. Infested leaflets curl and thicken, forming small “pod galls” instead of expanding normally. Inside each pod gall, two to eight cream-colored larvae or pupae may be found. After the adult midges emerge, the galls drop leaving bare leaf stalks.

The honeylocust podgall midge has multiple annual generations, being most active from the time of first shoot growth through mid-summer. Infestations occasionally can be severe enough to temporarily destroy all new growth. Leaflets that have already expanded are not injured by the insect. All commonly planted honeylocust varieties appear to be susceptible to honeylocust podgall midge.

Natural honeylocust podgall midge controls include severe weather and a small parasitic wasp that attacks young midge larvae. Heavy midge infestations often collapse when new growth ceases and the trees are no longer attractive to the egg-laying adult midges. In the absence of suitable egg-laying sites, the adult midges apparently go into an inactive diapause stage, renewing activity the following spring.

Chemical controls have been only moderately effective. Some reduction of gall production can result from applications of Diazinon, Dursban or Mavrik applied during egg-laying periods. Control of the earliest midge generations are most important since they are present when most leaf growth is produced. The first generation appears in spring with the first flush of new growth. The second and subsequent generations follow at about three to four week intervals. Insecticide applications need to be renewed regularly to protect the newly expanding leaflets. Insecticidal control often is poor if egg laying is heavy.

(NOTE: Dimethoate (Cygon) is extremely phytotoxic to honeylocust and can cause serious leaf injuries.)

Honeylocust Spider Mite

The honeylocust spider mite is closely related and similar in habits to the common two-spotted spider mite. Both are barely visible to the unaided eye and feed on the undersides of leaves. During mid-summer, honeylocust spider mite populations
greatly increase and the foliage of infested trees turns a bronze color. Injured leaves often drop prematurely.

Regular watering during hot summer months should help reduce mite population build-up and lessen tree damage. Natural spider mite predators (predatory mites, predatory thrips) often contribute to a great reduction of mite populations by late August, but chemical controls may be needed to prevent injury. Fortunately, honeylocust spider mite is controlled more easily than the two-spotted mite that causes problems on other ornamental plants. Dicofol (Kelthane) and Orthene are among the most widely available miticides. Ven- dex, Mavrik and Pentac are alternative miticides available only to commercial pesticide applicators. Repeat applications of insecticidal soaps or spray oils also can be used effectively if proper precautions are taken to check first for potential plant injury.

(NOTE: Use of carbaryl (Sevin) and mala-thion have led to increased mite problems in Colorado State University trials.)

Eriophyid Mites

Minute eriophyid mites commonly are observed on honeylocust and are thought to contribute to leaf bronzing. Because these eriophyid mites occur on leaves (versus in galls), they are called “leaf vagrant” mites. Carbaryl (Sevin, etc.), Mavrik, insecticidal soaps, and most organophosphate (diazinon, malathion, etc.) insecticides control leaf vagrant eriophyid mites on honeylocust.

Plant Bugs

Honeylocust plant bugs commonly infest honeylocust in late spring. This common damaging species of plant bug is generally green in color and, when immature, superficially resembles an aphid. Injured foliage typically is discolored by yellow or brown spotting, leaves become twisted and twig dieback can occur during heavy infestations. New foliage is particularly favored by the plant bug. This insect can indirectly limit honeylocust pod gall midge by destroying gall-susceptible new growth. A single generation of these insects occurs with damage peaking in late May and early June.

Chemical controls are recommended only when spring growth is seriously threatened since regrowth occurs in June when insect populations diminish. Orthene, carbaryl (Sevin, tree and ornamental spray, etc.) and diazinon have been shown to control plant bugs.

A second, brown-colored species of plant bug also occurs on honeylocust. This is reported to limit feeding to flowers and developing seeds and is not damaging to honeylocust foliage.

Leafhoppers

A common species of green leafhopper infests honeylocust and many other trees. Peak populations of the leafhopper occur in late spring, often together with plant bugs. Visible damage caused by the leafhoppers is minimal and rarely results in more than a scattered yellow spotting of the foliage. Temporary honeydew problem also may occur during heavy infestations.

Leafhoppers on honeylocust appear to have one generation per year, however, some adult leafhoppers are found in late July. If necessary, leafhoppers easily are controlled with all commonly used shade tree insecticides (Sevin, orthene, diazinon, insecticidal soaps, etc.)

Blister Beetles

Ash-grey blister beetles suddenly may occur in large numbers on trees, occasionally causing serious defoliation over parts of the tree. Infestations tend to occur most frequently in late June or early July and end as suddenly as they begin. If severe defoliation is threatened, control can easily be accomplished using any of the insecticides commonly used for insect control on trees and shrubs (Sevin, diazinon, malathion, etc.)

Cottony Maple Scale

Cottony maple scale occasionally builds up in large numbers on branches and leaves of honeylocust becoming quite conspicuous as egg sacks swell in June and July. The overwintering stage of this scale (mated female) can be controlled with dormant oil applications made before new growth in spring. These treatments also can help suppress spider mites, eriophyid mites, and plant bugs that overwinter on trees. Newly hatched scale crawler stages generally are produced in late June through July and can be controlled at that time with application of diazinon, Sevin, malathion or orthene. Natural controls generally maintain cottony maple scale at nondamaging levels and sustained infestations are very rare.

Honeylocust Borers

The various honeylocust borers are metallic or longhorned beetles that spend larval stages tunneling under the bark. This injury is capable of contributing to honeylocust decline but borer problems are rarely the fundamental cause of honeylocust decline. Honeylocust borers only can attack and develop successfully within trees already stressed due to drought, root pruning, disease or other causes. Most borer activity occurs in areas of existing cankers. External evidences of a honeylocust borer infestation can be ‘weeping’ at wounds and the small circular-oval exit holes made by the adult beetles as they emerge from the trunk.

Proper watering, tree care, and in particular, prevention of wounding must be considered the most important techniques for reducing problems with honeylocust borers. Usually, this is sufficient. Supplemental insecticidal controls should consist of maintaining a protectant insecticide on the tree trunk during the insect egg-laying/egg-hatch period in early summer. Lindane and chlorpyrifos (Dursban) are used for control of related borers attacking other shade trees. The most common species in honeylocust are thought to emerge and lay eggs during June.
