ABSTRACT

INDICATIONS OF COMPLEX LITHOSPHERIC STRUCTURE AROUND THE CHEYENNE

BELT IN THE WESTERN U.S. BASED ON SHEAR WAVE SPLITTING ANALYSIS

This study employs the method of shear wave splitting using a modified *Silver and Chan* methodology to produce constraints on the character of the upper mantle below the Cheyenne Belt suture zone (CB), North America. The CB marks the boundary between the Proterozoic Yavapai and Archean Wyoming Provinces. A previously undetected regional anisotropic fossil fabric with north trending fast axis orientations was detected in topographically low areas and interpreted produced by Proterozoic strain created during the convergence that produced the CB. Anisotropy results sub-parallel to absolute plate motion (APM) were detected in the mountainous areas.   This is interpreted as caused by local post-Laramide heating of the lithosphere, which has reset Proterozoic anisotropy.   This interpretation explains the complexity of shear wave splitting noted in Colorado by other studies.

ACKNOWLEDGEMENTS

I must express my sincere gratitude to my advisor, Derek Schutt, for his patience, friendship and guidance as he taught me to view the earth as a geophysicist. I would also like to thank my committee member Jay Breidt for his time, effort and statistical expertise he has brought to our research. And, of course, Judy Hannah, whose friendly face and kind demeanor the first time I came to CSU to learn about the geosciences program represented the college so well, that I quickly quit my job and enrolled. Finally I want to thank my fellow student and officemate Jamie Pierce for the friendship and long discussions about difficult geophysical concepts.

TABLE OF CONTENTS

LIST OF TABLES

CHAPTER 1

1.1 Introduction

This work describes the methods and results of shear wave-splitting research performed on the Cheyenne Belt region of southern Wyoming and northern Colorado, North America. Seismic data was analyzed using the Transverse Component Minimization Method devised by *Silver and Chan* [1991] to determine subsurface anisotropic characteristics.

1.2 Organization of Thesis

This thesis follows a three-part configuration. Chapter one is intended to inform audiences unfamiliar with seismic anisotropy, seismic phase paths, and the method of shear wave splitting such that they can better appreciate this work as a whole. Chapter two is written in a form potentially acceptable for submission to a peer-reviewed journal, likely the American Geophysical Union's Journal of Geophysical Research. Chapter three offers advice for the direction of future research.

1.3 Anisotropy

A material is described as isotropic with respect to a physical property if the property shows no directional dependence. As an example, the velocity of light in glass is isotropic. Consequently, when viewing a dot on a piece of paper through glass, the dot does not change in appearance or location as the glass as rotated (Fig. 1.1A). An anisotropic substance has a physical property that is directionally dependent, like the velocity of light in the mineral calcite. In the case of calcite, two dots will be seen as the light is split into two perpendicularly polarized waves. As the calcite is rotated 360° one dot will complete a circle around the other (Fig. 1.1B). Although it is difficult to detect, the light travelling along one plane travels faster than the other.

In a similar way, parts of the earth exhibit seismic velocity anisotropy.   When a shear wave

encounters an anisotropic layer, it can be split into two near-perpendicular waves, one

propagating faster than the other.   This phenomenon, called shear-wave splitting (SWS), can be

characterized through two parameters: ɸ (phi) – the azimuth of the fast plane, and δt (delta t)–

the time in seconds between the arrival of seismic energy on the fast plane and its arrival on the

slow plane.

Certain minerals common to the Earth's mantle exhibit anisotropy. Of these the most

important is olivine (Fig. 1.2). In parts of the mantle, very roughly above 200 km depth, olivine

is expected to deform through a mechanism called deformation creep, which causes the olivine

grains in the mantle to align preferentially in a particular direction [*Hess*, 1964]. In many cases,

olivine crystals will become oriented such that their fast axis is parallel to the primary strain axis.

In this way a measurement of anisotropy in the mantle is a proxy for a measurement of the

direction of strain, which may be the result of ongoing mantle flow or past episodes of

deformation.

Anisotropy is also common in Earth's crust, where it can be caused by preferential

alignment of cracks or minerals.   Thicknesses involved in crustal anisotropy are much smaller

than those in the upper mantle, so the crustal component of an anisotropic measurement is

assumed to be negligible [*Long and Silver*, 2009].

1.4 Detection of Anisotropy

Of all the S wave phases, ones that travel through the Earth's outer core are particularly

useful. The outer core is liquid, so it cannot support the shear stress of an S wave. When an S

wave reaches the core-mantle boundary some of its energy is converted into a P wave (Fig.

1.3A). This conversion removes any information the wave may have been carrying about

anisotropy it encountered along its downward path from an earthquake's epicenter to the core. As the P wave exits the outer core some of its energy produces a new S wave containing no anisotropic information and with a known orientation related to the azimuth from the seismometer to the earthquake. When detected by a seismometer, any information about anisotropy is known to have developed when it encountered anisotropic material on its upward path from the core-mantle boundary to the seismometer. For this reason, the most common S wave phases used to detect mantle anisotropy are the SKS the SKKS and the PKS (hereafter called *KS) (Fig. 1.3B).

Seismologists often work in a coordinate system defined by the direction from the seismometer to the earthquake that produced an observed seismogram known as the back-azimuth (Figure 1.4). To enable the isolation of the energy from a *KS phase, waveforms are converted from the north, east and vertical orientation (the Global Reference Frame) recorded by a seismometer to a radial, transverse and vertical orientation (the Event-Station Reference Frame) (Figure 1.5).

As a consequence of their paths, *KS phases start their upward leg polarized in the radial plane (Figure 1.6). Detection of anisotropic material along the upward leg of the *KS phases path will occur if the material exists, and if the radial plane of the *KS phase does not align with the material's fast or slow axes (Figure 1.7). Approaches from angles not aligned with the material's fast or slow axes produce varying amounts of anisotropy with the amount of observed transverse energy maximized for approaches equiangular between the fast and slow axes i.e. 45°, 135°, 225° and 315°.

1.5 Notable Contributors to the Detection of Anisotropy

Notable contributions to the science of S phase analysis to infer mantle flow include *Turner* [1942] who documented the preferred orientations of olivine crystals during deformation; *Verma* [1960] who determined the fast and slow axes of olivine crystals; *Hess* [1964] who demonstrated that inferences about mantle flow based on anisotropy analysis can be geophysically defensible; *Vinnik et al.* [1984] who first used the SKS phase for anisotropy detection; and *Silver and Chan* [1991] who proposed the concept of lithospheric "fossil" anisotropy related to the last major regional deformation event for continental interiors.

1.6 The Silver and Chan Method

The most popular method for the study of seismic anisotropy has been the Transverse Component Minimization Method [*Silver and Chan*, 1991], often just called the Silver and Chan method. This method assumes that detected anisotropy is the result of a single flat layer of anisotropic material with a constant fast axis orientation, and that input *KS waves are vertically incident. Data are rotated from North/South and East/West components to radial and transverse components. Seismic energy on both the radial and transverse components is a positive indicator for anisotropy (unless the ray path is bent off the great circle path), much like the two dots viewed through calcite. This method then determines which values of ϕ and δt are most capable of removing all energy from the transverse component. When found, the ϕ value approximates the azimuth of the fast axis of the anisotropic material, and the δt value is the time difference between the fast and slow-polarized waves. Actual δt values are proportional to the product of the thickness of encountered anisotropic material and the degree of alignment between *KS wave's propagation direction and the material's fast axis.

The assumption that a *KS wave will only encounter a single anisotropic layer of material that has a constant fast axis orientation is a sizeable oversimplification of the earth's upper mantle. It is more likely that a *KS wave will encounter multiple layers of anisotropic material, each with varying degrees of anisotropy, and varying strikes and dips. This variety of orientation and material properties introduces considerable complexity to the *KS waveform. Synthetic waveforms demonstrate the relative simplicity of a *KS waveform altered by a single layer of anisotropic material (Fig. 1.8A), and the complexity of a *KS waveform altered by two layers of anisotropic material (Fig. 1.8B).

1.7 Study Site

Anisotropy studies using *KS data have been conducted all over the world (Fig. 1.9). The focus of this study is the Cheyenne Belt, a mid-continent suture zone in North America where subduction of oceanic lithosphere drew closer and attached 1.8 Ga island arcs to the ~ 2.5 Ga Wyoming Province (Fig. 1.10). Most of Colorado rests on the Yavapai Province, the result of the addition of these volcanic arc fragments to the growing North American continent (Fig. 1.11).

1.7.1 The Wyoming Province

The Cheyenne Belt separates the Archean Wyoming Province to the north from the Proterozoic Yavapai Province to the south. It is a Proterozoic suture zone expressed as a multi-fault, northeast striking, subvertical shear zone [*Sullivan and Beane*, 2013]. The Wyoming Craton is composed of five main subprovinces, each with a unique history (Fig. 1.12).

The Sweetwater Subprovince is at least 2.9 Ga old. It likely had an active southern margin based on recorded periods of magmatism, basin formation and deposition and shortening [*Chamberlain et al.*, 2003].

5

The Sierra Madre – Medicine Bow exotic block appears allocthonous to all other parts of the Wyoming Craton and was likely accreted to the southern margin of the Sweetwater Subprovince no earlier than 2.62 Ga [*Chamberlain et al.*, 2003].

The Hartville – Black Hills block formed to the east of the Sweetwater Subprovince and is different than the rest of the Wyoming Province with both Archean and Proterozoic basement rock. It accreted to the southeastern margin of the Sweetwater Subprovince no earlier than 2.55 Ga [*Chamberlain et al.*, 2003].

These subprovinces, together with the Bighorn and the Montana Metasedimentary subprovinces to the north, compose the Wyoming Craton, which together with the Slave, Rae, Hearne and Superior cratons make up the Precambrian Laurentian Shield (or Laurentia) [*Whitmeyer and Karlstrom*, 2007]. Between 2.45 – 2.1 Ga Laurentia was a part of the supercontinent Kenorland, along with the continents Baltica, Australia and Kalahari [*Pesonen et al.*, 2003].

Rifting, possibly related to the breakup of Kenorland, along the southern margin of the Wyoming Craton, affecting the three Wyoming Craton subprovinces contacting the Cheyenne Belt, occurred between 2.1 and 2.0 Ga forming a passive margin [*Pesonen et al.*, 2003], [*Chamberlain et al.*, 2003]. This passive margin accumulated ~300 Ma of sediments before its activation and closure [*Yuan and Dueker*, 2005].

1.7.2 The Yavapai Province

Formation of the next supercontinent might be associated with the subduction south of the Wyoming Craton that produced accretion of the Yavapai Province. Between 1.83 – 1.25 Ga the continents Laurentia, Baltica, Ukraine, Amazonia, Australia and possibly Kalahari, Siberia and North China came together to form Hudsonland (also called Columbia and Nuna) [*Pesonen et*

al., 2003]. The occurrence of common features, geological belts and magmatic intrusions, along with paleomagnetic data support the hypothesis that subduction south of the Wyoming Craton may have subducted oceanic lithosphere - containing subduction related island arc terrains - that separated Laurentia from Australia [*Pesonen et al.*, 2003].

The location of synsubduction magmatism offshore in oceanic lithosphere south of the Wyoming Craton, rather than inboard or bordering the Wyoming Craton indicates that subduction was primarily south dipping. However, an anomalously high velocity region north of the Cheyenne Belt dipping to the north at 45° with an 80 km width [*Yuan and Dueker*, 2005] cannot be explained with simple south dipping subduction. It is called the Wyoming slab and at least two solutions have been proposed to explain this anomaly, both including a temporary cessation of south dipping subduction due to the accretion of two substantial island arc bodies called the Green Mountain Arc (GMA) and the Rawah Arc (RA). In the first solution south-dipping subduction brings the GMA into collision with the Wyoming Craton's southern margin. The force of the collision, and the buoyancy of the GMA, force remaining oceanic lithosphere north under the Wyoming Craton in a north dipping orientation producing the Cheyenne Slab [*Tyson et al.*, 2002]. In the second solution south-dipping subduction brings both the GMA and RA into collision with the Wyoming Craton, but north-dipping subduction occurs south of the RA. Subducted volatile related magmatism then produced a ~200 km wide back-arc basin between the GMA and RA. Under further subduction pressure the back-arc basin was subducted with a north dipping orientation producing the Cheyenne Slab [*Yuan and Dueker*, 2005].

Both solutions require a flip of the orientation of subduction, i.e. south dipping subduction switching to north dipping subduction. A modern analog for a flip in subduction orientation exists where the Banda arc and the Australian plate converge. [*Yuan and Dueker*, 2005].

The accretion of more subduction related island arc terrains followed the collision of the GMA and RA to the Wyoming Craton and placement of the Cheyenne Slab. Marine arc related sediments are found in regions of the Yavapai Province including ophiolites, pillow basalts and turbidites [*Whitmeyer and Karlstrom*, 2007]. Near the end of the formation of the Yavapai Province it was deformed by northwest – southeast shortening causing crustal thickening due to continued subduction of island arc terrains. Granitic plutons were formed in the western Yavapai as a result of north dipping subduction. Together these forces produced metamorphism related to burial depths of 10 – 20 km and large lateral temperature gradients [*Karlstrom and Williams*, 2006].
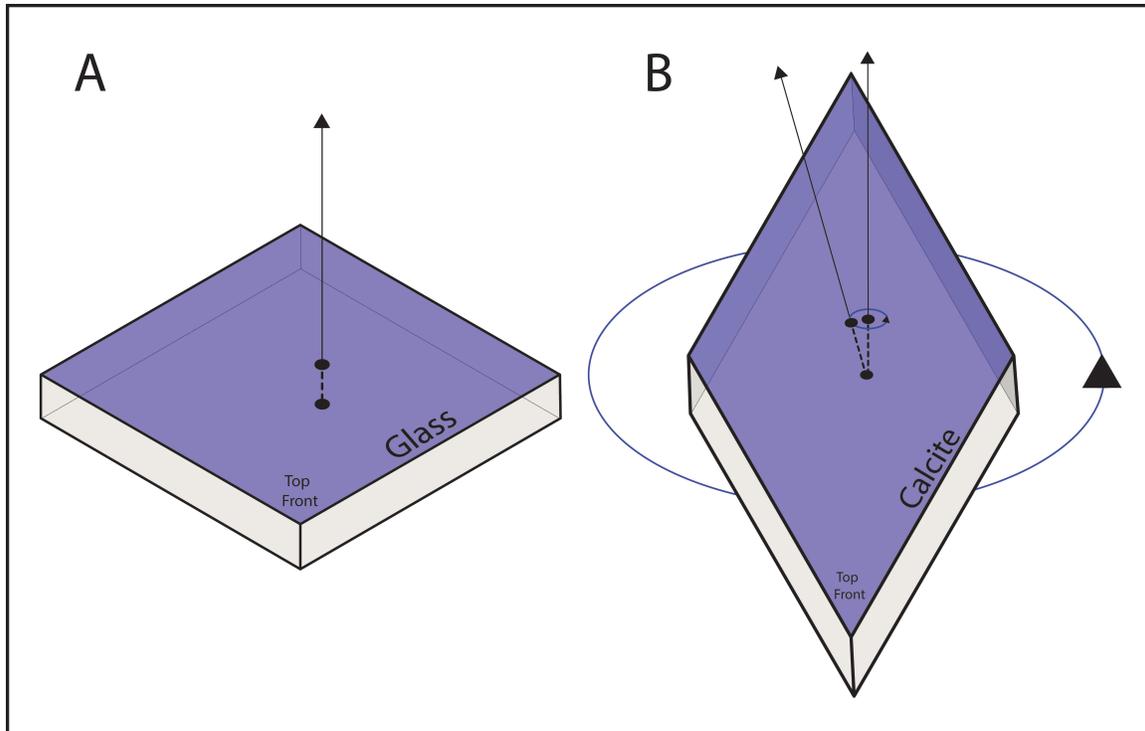

Figure 1.1. A demonstration of the effects of light travelling through isotropic and anisotropic material. Each material is placed on a piece of paper where a dot has been drawn. A. The isotropic material, in this case glass, transmits a single refraction of the dot regardless of how the glass is moved. B. When the same procedure is conducted with an anisotropic substance, like calcite, two refractions are produced by the material. The material has split the light into two separate orientations. As the calcite is rotated, one of the refracted circles will appear stationary as the other rotates around it. Measurements of the refracted light through calcite are dependent on the orientation of the material.
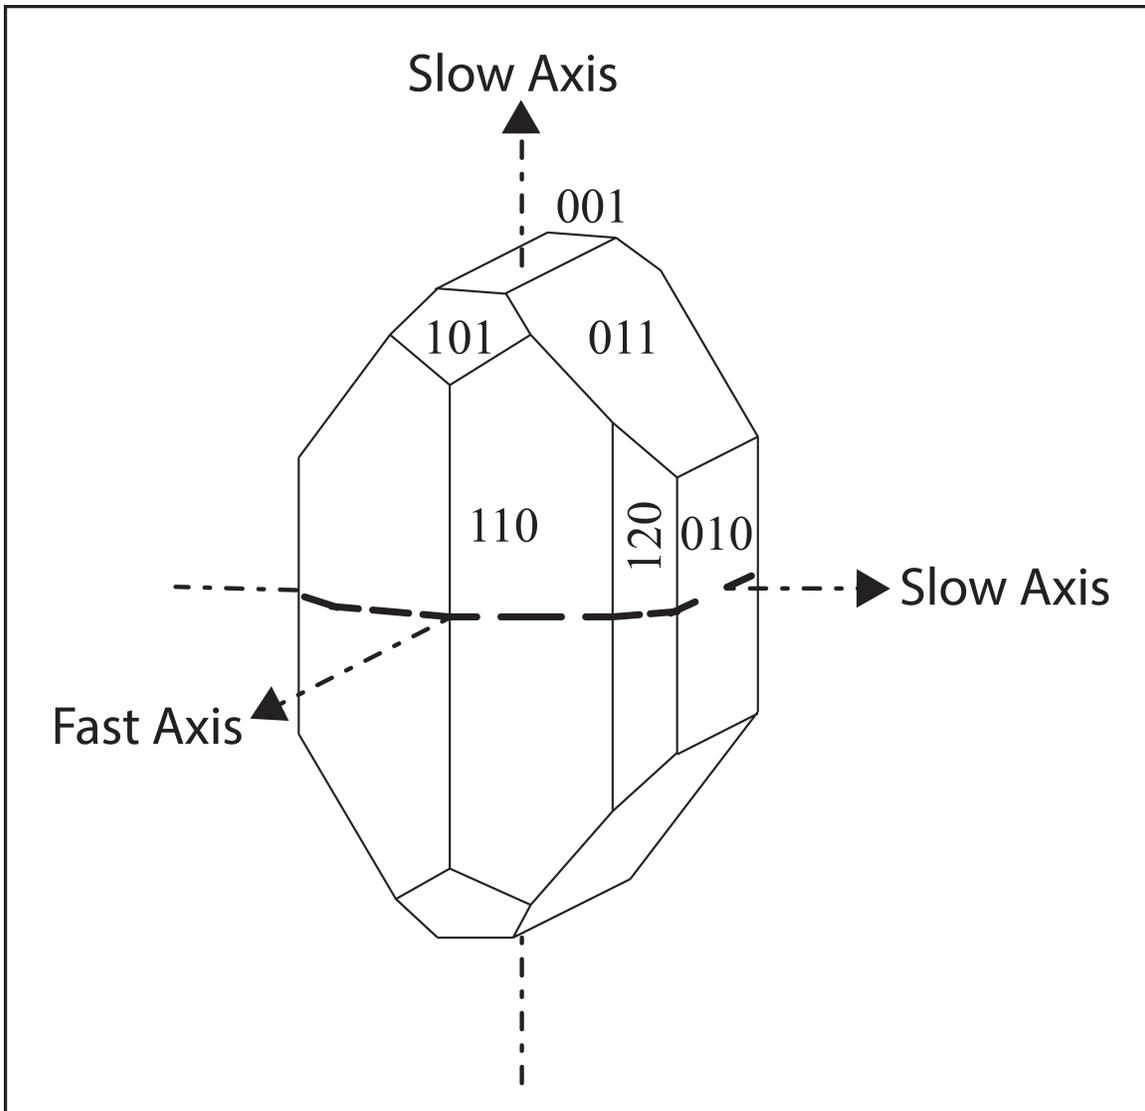

Figure 1.2. This is a crystallographic depiction of an olivine crystal. It has been shown that in most circumstances in the Earth's upper mantle that olivine crystals affected by a strain will become oriented so that the crystal's fast axis is parallel to the primary strain axis.   After *Nesse* [2004].
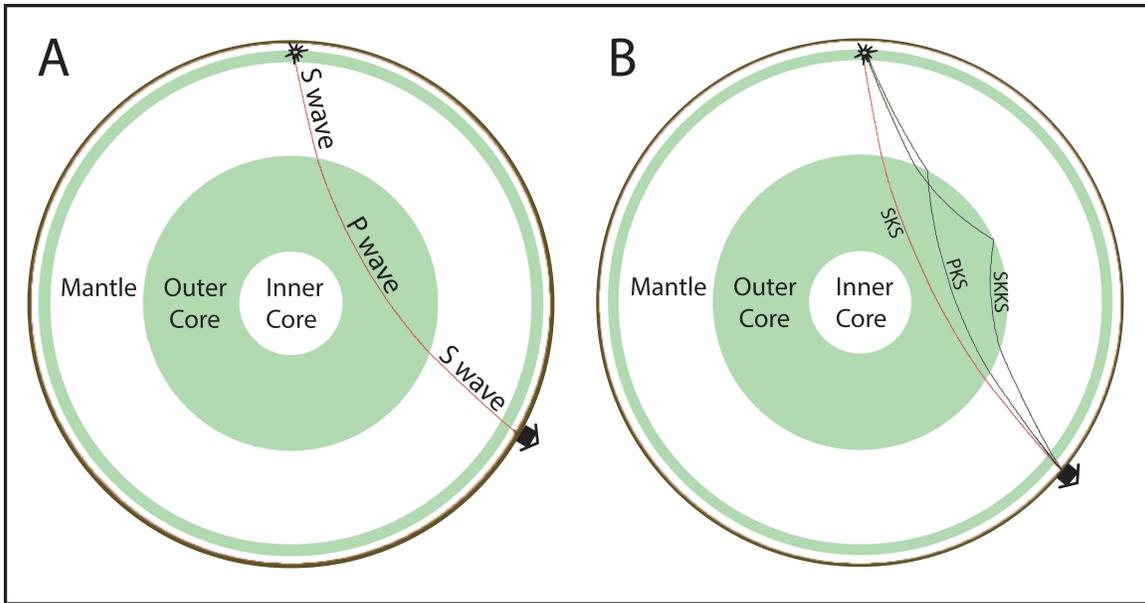

Figure 1.3. A. Depiction of an SKS wave. This wave begins as an S wave, but some of its energy is transferred to a P wave when it encounters the Earth's outer core. The outer core is liquid and does not support S wave particle motion. Any information about anisotropy the original S wave collected prior to its encounter with the outer core is lost when some of its energy becomes a P wave. When the P wave reaches the mantle, some of its energy becomes a new S wave. In this way, any anisotropy detected from an SKS wave is known to have occurred in the mantle between the outer core and the seismometer. B. Depiction of the phases used in this study: SKS, PKS, SKKS. After *Crotwell* [1999].
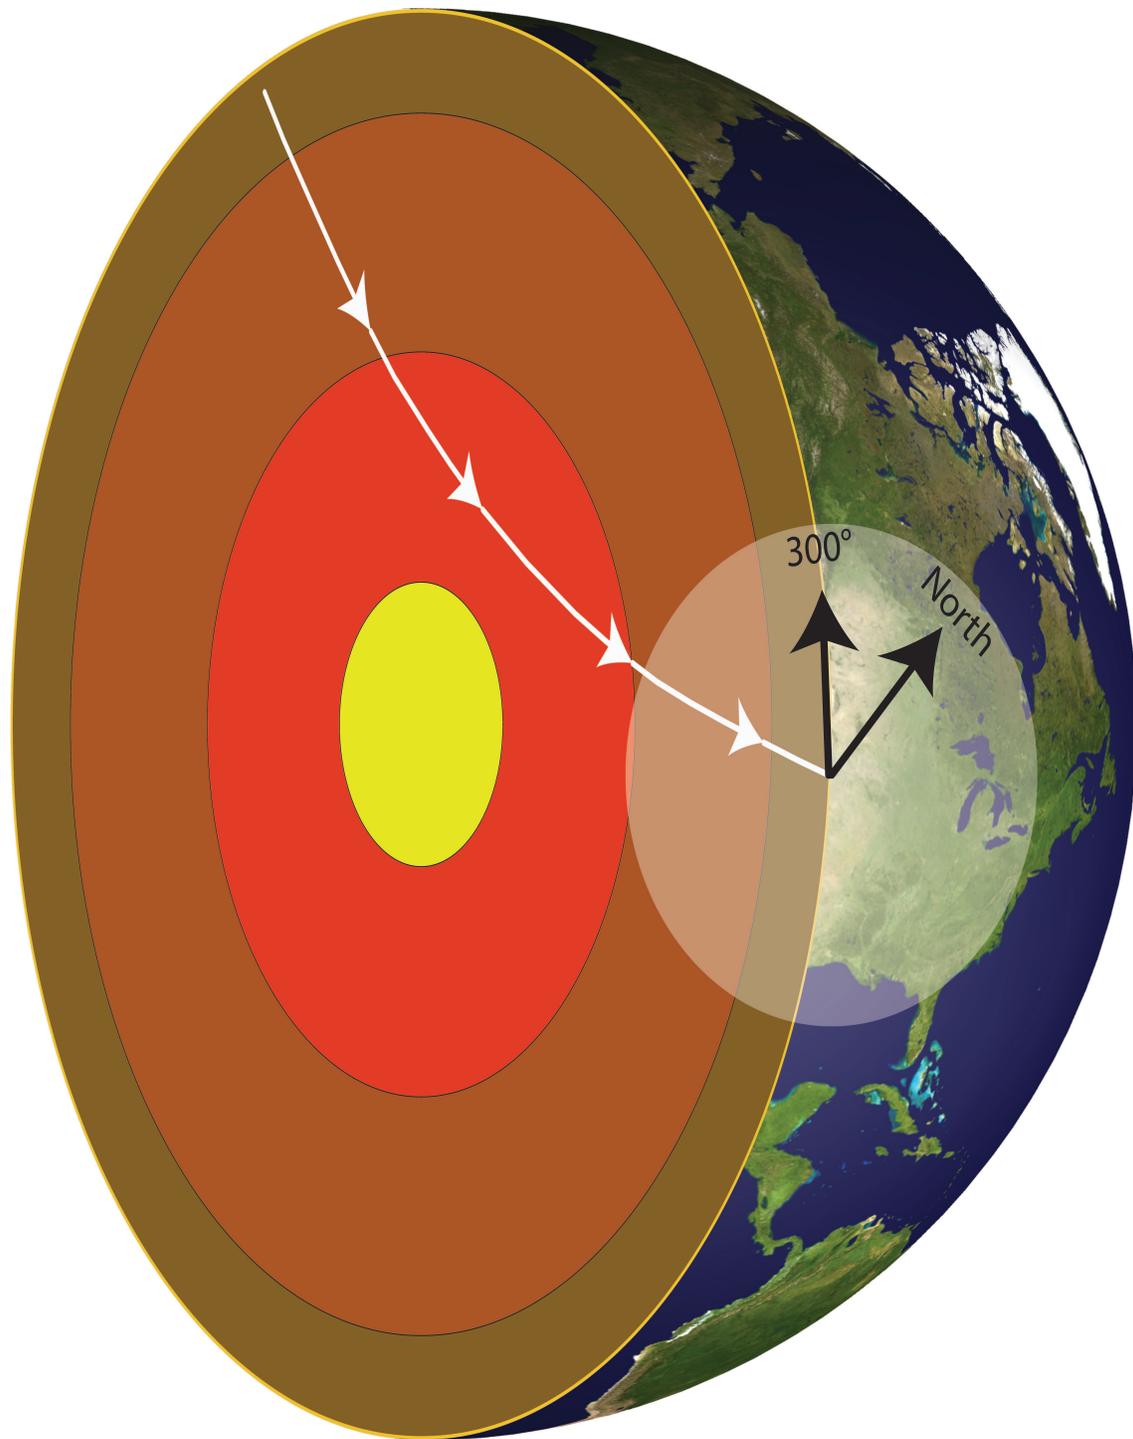

Figure 1.4. A seismic signal's back azimuth is defined as the azimuth from the seismometer to the epicenter of the source. White line depicts the path of an SKS phase as it travels through the earth. Back-azimuth arrow (300°) indicates the direction from the seismometer back to the earthquake epicenter.
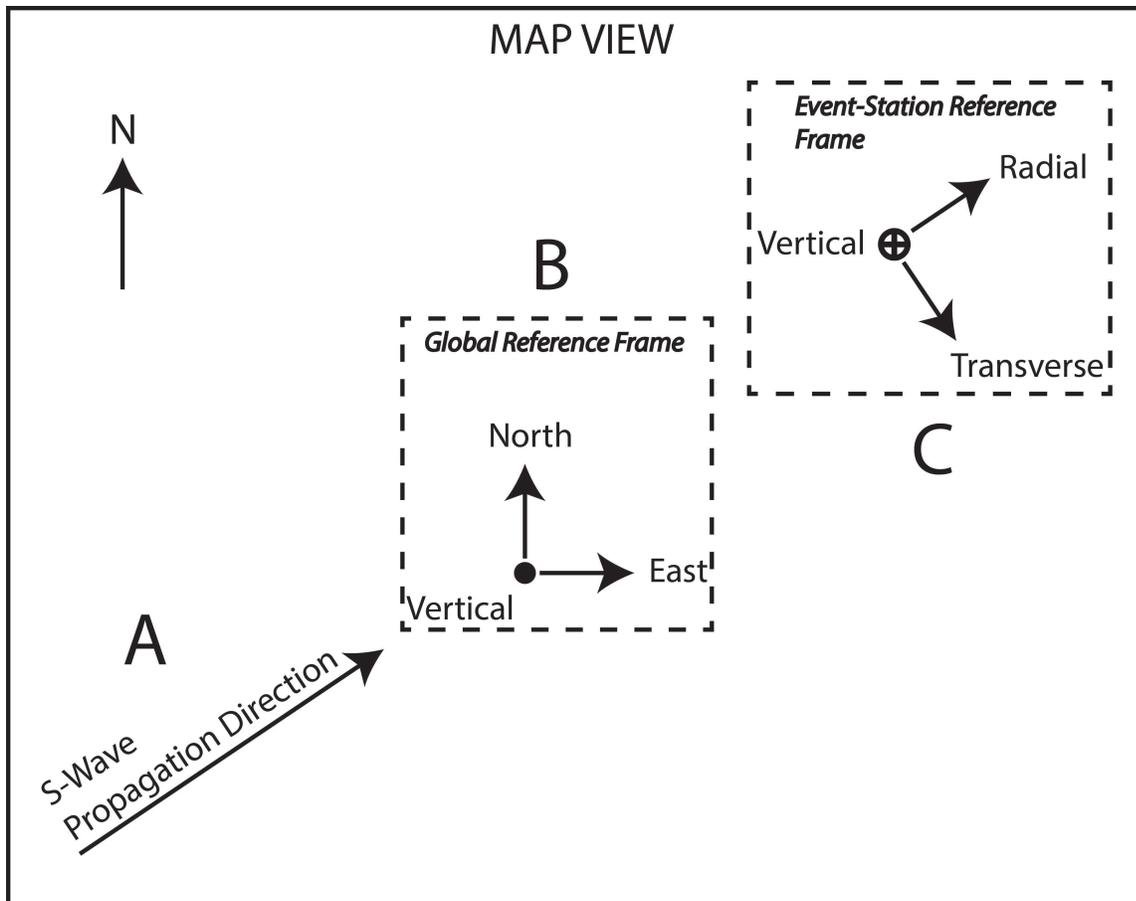

Figure 1.5. Seismic data orientation. A. The orientation of an incoming seismic signal. B. The seismometer records the signal using a global reference frame. C. Data is moved to an event-station reference frame for further processing.
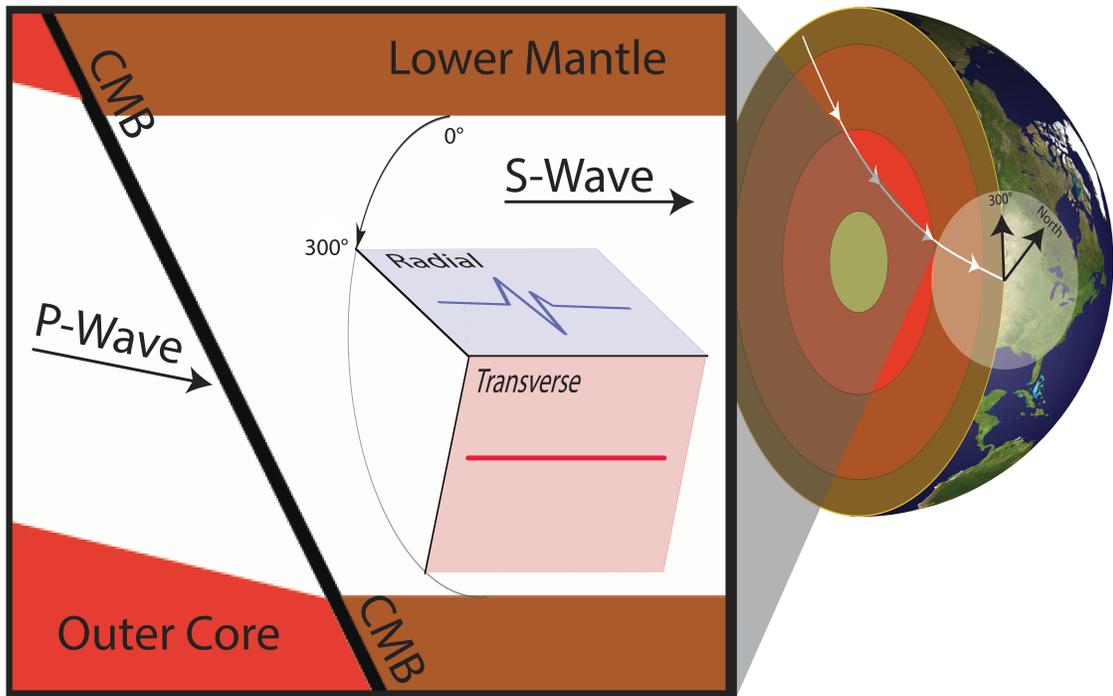

Figure 1.6. White regions represent the path of P wave and S wave propagation. As the P wave, approaching from a back-azimuth of 300° passes the CMB (core mantle boundary) some of its energy is converted into an S wave. All of the energy in this new S wave produces particle motion perpendicular to the wave's direction of propagation, and in the radial plane. The great circle path produced by the radial plane's intersection with the surface of the earth is oriented along the event-station back azimuth.
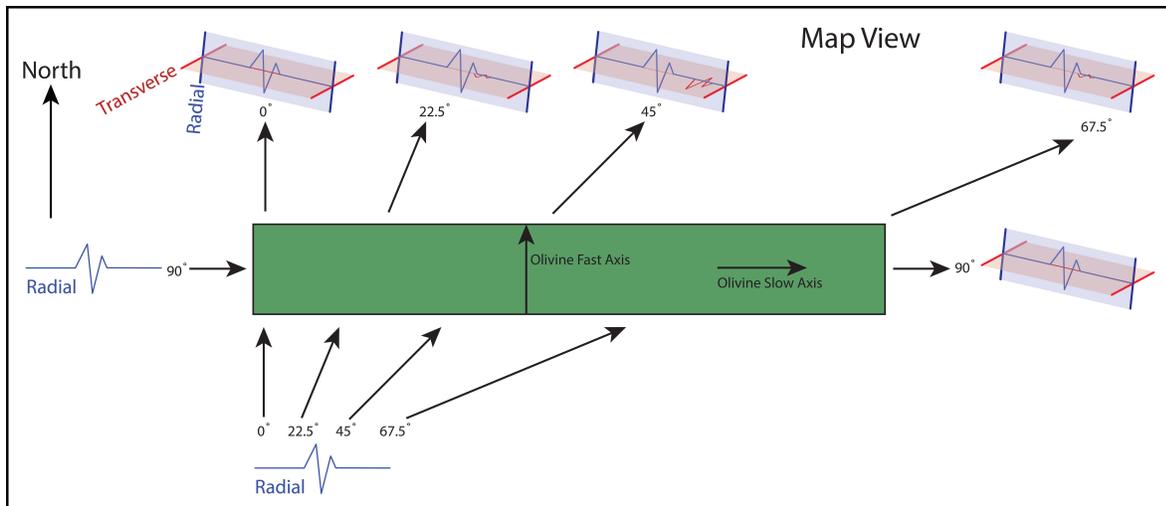

Figure 1.7. Depictions of effects of back azimuth on SKS splitting. Note: the fast axis of the anisotropy is 0°. For SKS waves approaching from back azimuths parallel and perpendicular to 0°, for example 0° and 90°, the transverse wave contains no energy—a result indistinguishable from the case with no anisotropy.   The maximum transverse component energy is found for back azimuths midway between 0° and 90°, at 45°. From 0° to 45° the anisotropic effect on transverse energy increases, while from 45° to 90° the effect diminishes. This example uses only the first quadrant of the Cartesian plane. The same pattern occurs in the other three planes so that no anisotropic effect occurs when the SKS wave approaches from 0°, 90°, 180° and 270°, while the maximum effect occurs at 45°, 135°, 225° and 315°.

A One Layer

B Two Layer

16
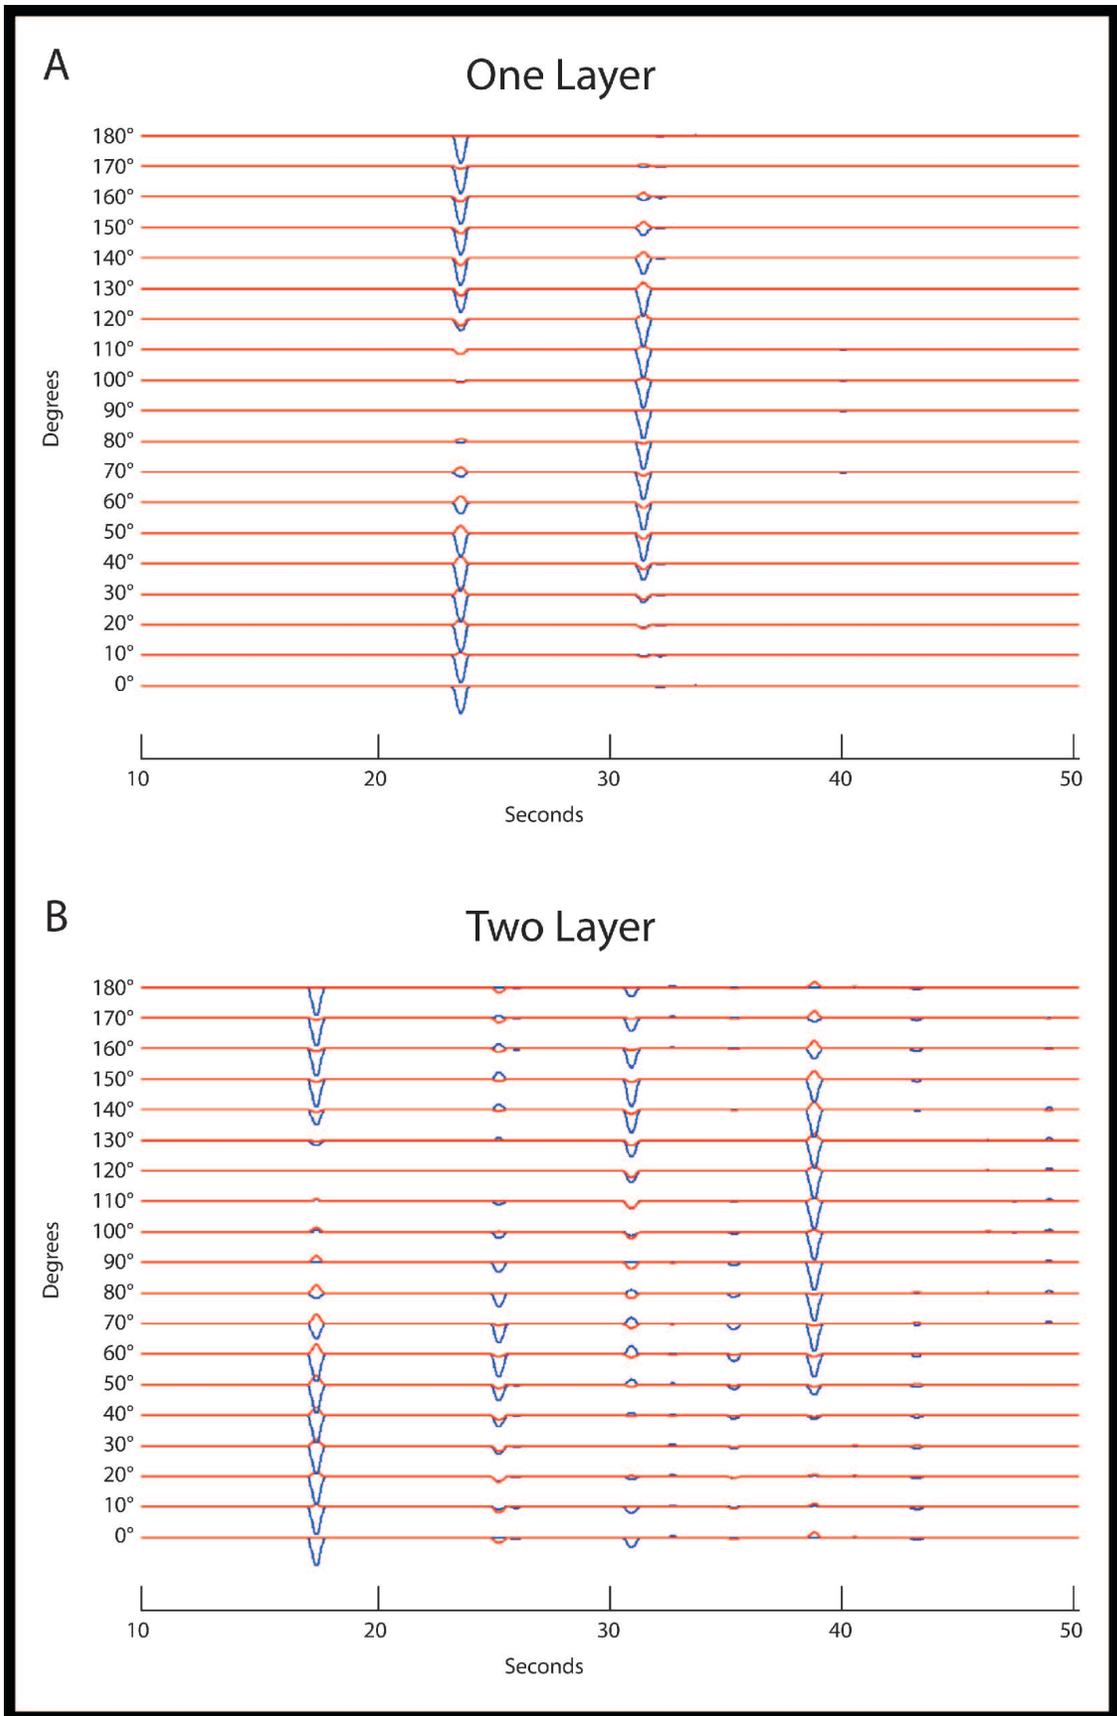

Figure 1.8. Synthetic seismograms. These are highly simplified synthetic impulse response seismograms. Convolving these seismograms with a ricker wavelet and adding random noise can produce more realistic complexity. In both figures blue depicts radial energy, and red depicts transverse energy. The x-axis is an arbitrary time scale that is common to both figures. The y-axis is the back azimuth in degrees. A. Synthetic seismograms of *KS wave encountering a single layer of anisotropic material with a strike of 0° and a dip of 0°. Waves approaching from back azimuths of 0° and 180° incur no shear wave splitting. All energy traversed the material's fast axis and remains on the radial component (the pulses at ~ 23 s). Waves approaching from back azimuths of 90° and 270° (not shown) also incur no shear wave splitting, but all energy traversed the material's slow axis and remains on the transverse component (the pulses at ~ 32 s). Waves approaching from all other back azimuths incur varying degrees of shear wave splitting as their energy transits both the fast and slow axes. B. Synthetic seismograms of *KS wave encountering two layers of anisotropic material. Layer 1: strike of 0°, dip of 0°, Layer 2: strike 30°, dip of 0°. When the *KS wave encounters the lower layer of anisotropic material (Layer 2), splitting does not occur for back azimuths of 30°, 120°, 210° and 300°. Splitting does occur to a varying degree for all other back azimuths. Waves exit the lower layer, either split or not split, and enter the upper layer of anisotropic material (Layer 1). Here further splitting occurs for all waves not parallel to the upper layer's fast or slow axes.
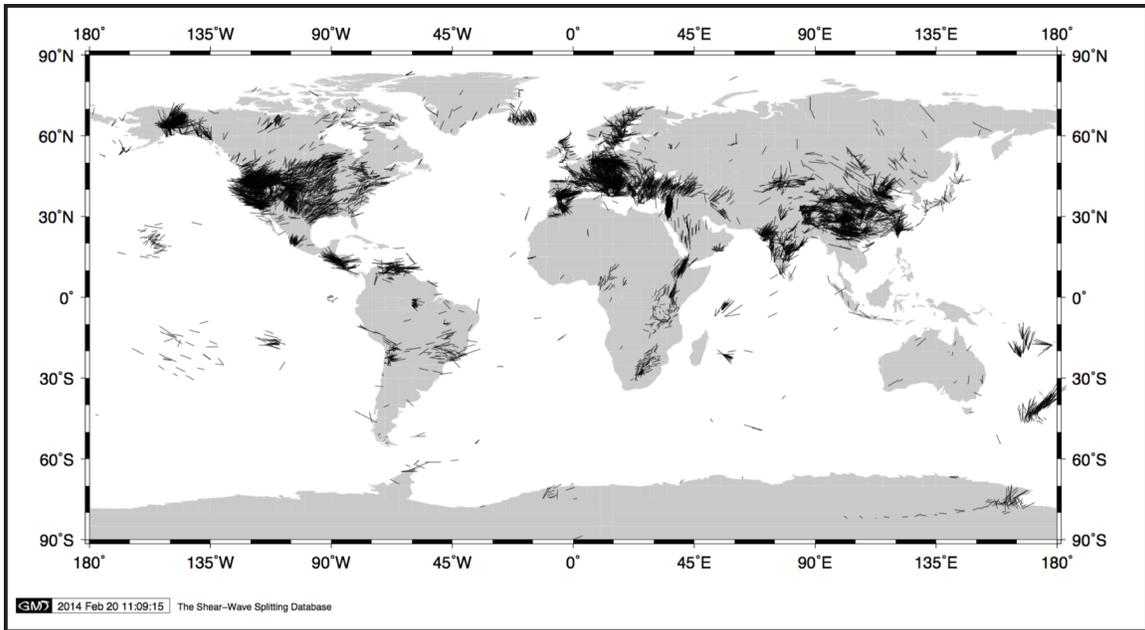

Figure 1.9. Map of some of the shear wave splitting results released in peer-reviewed journals. Each black line indicates a shear wave splitting result. The line orientation informs of the direction of anisotropy while the length of the line is related to the degree of anisotropy. [*Wüstefeld et al.*, 2009]

CHAPTER 2

INDICATIONS OF COMPLEX LITHOSPHERIC STRUCTURE AROUND THE CHEYENNE

BELT IN THE WESTERN U.S. BASED ON SHEAR WAVE SPLITTING ANALYSIS

2.1 Introduction

The Cheyenne Belt is a major North American suture zone where Proterozoic island arc

terrains were accreted onto the Archean Wyoming Province between 1.80 and 1.70 Ga

[*Whitmeyer and Karlstrom*, 2007] (Fig. 2.1). In this study, the portion of the Cheyenne Belt in

southeastern Wyoming was investigated. Here, the Cheyenne Belt bends from a north-northeast

trajectory to a west-southwest trajectory.

North of the Cheyenne Belt the Wyoming Province underlies most of Wyoming and the

adjacent states. South of the Cheyenne Belt the Yavapai Province underlies most of Colorado.

The Cheyenne Belt remains a detectable, and in some places very complex, expression of

southern lithospheric growth of Laurentia during the Proterozoic.

The seismic technique of shear wave splitting (SWS) exploits the anisotropic characteristic of

certain minerals, primarily olivine, found in the earth's mantle. Research has determined that

dislocation creep, thought to be the dominant deformation mechanism in the uppermost mantle,

aligns olivine with its fast axis parallel to the maximum strain direction via a lattice preferred

orientation (LPO) [*Long and Silver*, 2009] (Fig. 2.2).   Core phases, particularly SKS, PKS and

SKKS (hereafter called *KS) are useful because the effects of any event-side anisotropy are lost

as some of the S wave energy is converted into P wave energy at the core-mantle boundary

(CMB) (Fig. 2.3). When the P wave exits the outer core, some of its energy is converted to a

new radially polarized S wave with a known orientation dictated by the wave's back-azimuth, and initially no anisotropic effects. Once recorded by a seismometer, the *KS wave can be converted from the north, east and vertical reference frame used by the seismometer to the radial, transverse and vertical reference frame. In this orientation all *KS energy exiting the core will be on the radial channel. Energy found on the transverse channel indicates probable anisotropy between the core-mantle boundary (CMB) and the seismometer. Detected anisotropy is then considered to be the integrated effects of all anisotropic material the S wave encountered from CMB to seismometer. Measurements of shear wave splits (SWS) are often quantified with the parameters (ϕ) fast-axis orientation and (δt) delay time between fast axis and slow axis arrivals.

The in situ mantle below the continents is inaccessible to direct observation. Observations based on olivine anisotropy, detected through SWS, are one way to infer mantle flow characteristics and lithospheric fossil strain orientations. With these observations we hope to provide new constraints on the region surrounding the Cheyenne Belt that will improve our understanding of this Proterozoic suture zone.

2.2 Site Description

The Cheyenne Belt separates the Archean Wyoming Craton to the north from the Proterozoic Yavapai Province to the south. It is a Proterozoic suture zone expressed as a multi-fault, northeast striking, subvertical shear zone [*Sullivan and Beane*, 2013].
Rifting, possibly related to the breakup of Kenorland, along the southern margin of the Wyoming Craton occurred between 2.1 and 2.0 Ga forming a passive margin [*Pesonen et al.*, 2003], [*Chamberlain et al.*, 2003]. This passive margin accumulated ~300 Ma of sediments before its activation and closure [*Yuan and Dueker*, 2005].

Between 1.83 – 1.25 Ga the continents Laurentia, Baltica, Ukraine, Amazonia, Australia and possibly Kalahari, Siberia and North China came together to form the supercontinent Hudsonland (also called Columbia and Nuna) [*Pesonen et al.*, 2003]. The occurrence of common features, geological belts and magmatic intrusions, along with paleomagnetic data support the hypothesis that subduction south of the Wyoming Craton may have subducted oceanic lithosphere, containing subduction related island arc terrains, that separated Laurentia from Australia [*Pesonen et al.*, 2003].

The location of synsubduction magmatism offshore in oceanic lithosphere south of the Wyoming Craton, rather than inboard or bordering the Wyoming Craton indicates that subduction was primarily south dipping. However, an anomalously high velocity region north of the Cheyenne Belt dipping to the north at 45° with an 80 km width [*Yuan and Dueker*, 2005] cannot be explained with simple south dipping subduction. It is called the Wyoming slab and at least two solutions have been proposed to explain this anomaly, both including a temporary cessation of south dipping subduction due to the accretion of two substantial island arc bodies called the Green Mountain Arc (GMA) and the Rawah Arc (RA). In the first solution south-dipping subduction brings the GMA into collision with the Wyoming Craton's southern margin. The force of the collision, and the buoyancy of the GMA force remaining oceanic lithosphere north under the Wyoming Craton in a north dipping orientation producing the Cheyenne Slab [*Tyson et al.*, 2002]. In the second solution south-dipping subduction brings both the GMA and RA into collision with the Wyoming Craton, but north-dipping subduction occurs south of the RA. Magmatism related to subducted volatiles then produced a ~200 km wide back-arc basin between the GMA and RA. Under further subduction pressure the back-arc basin was subducted with a north dipping orientation producing the Cheyenne Slab [*Yuan and Dueker*, 2005].

Both solutions require a flip of the orientation of subduction, i.e. south dipping subduction switching to north dipping subduction. A modern analog for a flip in subduction orientation exists where the Banda arc and the Australian plate converge [*Yuan and Dueker*, 2005].

The accretion of more subduction related island arc terrains followed the collision of the GMA and RA to the Wyoming Craton and placement of the Cheyenne Slab. Marine arc related sediments are found in regions of the Yavapai Province including ophiolites, pillow basalts and turbidites [*Whitmeyer and Karlstrom*, 2007]. Near the end of formation the Yavapai Province was deformed by northwest – southeast shortening causing crustal thickening due to continued accretion of island arc terrains. Granitic plutons were formed in the western Yavapai as a result of north dipping subduction. Together these forces produced metamorphism related to burial depths of 10 – 20 km and large lateral temperature gradients [*Karlstrom and Williams*, 2006].

2.3 Data

Data used in this study came from broadband seismometers located between 39° and 42° north, and 105° and 109° W. This included the seismic arrays CD-ROM, Lodore, Laramie, CDROM, CREST and Earthscope transportable array stations, for a total of 235 sites. Using the Standing Order for Data (SOD) tool [*Owens et al.*, 2004], data for all SKS, SKKS, and PKS arrivals from M>5.8 earthquakes were reqested from the from the Incorporated Research Institutions for Seismology (IRIS) Data Management Center (DMC). Source distance ranges were 85-105°, 95-180°, and 125-150°, for the SKS, SKKS, and PKS, respectively.

2.4 Methods

Seismograms retrieved were visually inspected for a clear *KS arrival. An implementation of the [*Silver and Chan*, 1991] (SC) method for estimating the characteristics of seismic anisotropy was then applied. This method attempts to determine the combination of the

parameters δt and φ that best minimize transverse energy, thereby removing the effects of anisotropy. To accomplish this, a grid search is conducted over all reasonable pairings of δt and φ (δt values between 0 and 4 s; φ values between 0 and 180°) to find the most successful pair.

This implementation includes two modifications to the SC method. The first ensures that tangential energy is not over-corrected for by using a measurement of the pre-*KS tangential energy as the minimum corrected energy allowed. The second modification maps the corrected tangential splitting parameters into a probability density function for the identification a solution's confidence bounds.

Seismograms were then split into two groups based on the results of the SC method processing. Seismograms conforming to the following criteria were placed in Group (A):

- Signal to Noise Ratio > 2.5

- δt < 3.0 s

- δt error < 0.80 s

- φ error < 60.0°

Seismograms failing one or more of the criteria were placed in Group (B). Group (A) seismograms are considered the best data of this study. For this reason their splitting parameters were plotted without further processing. Group (B) seismograms, while not as good as those in Group (A), were still useful. They were combined with Group (A) seismograms, and stacked to improve signal to noise ratios and then plotted.

To stack the data, seismograms from stations were placed in two separate categories, depending on whether the stations were located north or south of the Cheyenne Belt. Then, the corrected transverse energy matrices from SC processing that define the transverse energy minimization for all combinations of δt and φ were summed using a Gaussian weight based on

distance from the station.   For instance, for the 40 km stacks, a Gaussian distribution that becomes asymptotic with 0 at 40 km was used.. The degrees of freedom for each SC result were also stacked, and used with the stacked corrected tangential energy to calculate the stacked confidence bounds using the F-test [*Schutt et al.*, 1998; *Wolfe and Silver*, 1998]

2.5 Results

From the data collected, 136 stations produced good quality data. Of those, 29 produced the best data (Table 1). Similarly, 102 events were considered to be of good quality while 32 of those were considered the best events (Table 2). A total of 334 good quality signals were found with 55 of those considered the best signals (Table 3). Back azimuths for these 32 best signals were primarily from 240 - 330° (Fig. 2.4);

The final four seismic anisotropy result sets, Group(A), 0 km stacks, 40 km stacks and 100 km stacks are each quite different, and the plot for each will be analyzed separately.

2.5.1 Unstacked Group(A) Plot

Many of the splits in Group(A) (Fig. 2.5), both north and south of the CB are aligned sub-parallel to the direction of absolute plate motion (APM) [*Larson et al.*, 1997]. However, splits less than 200 km north of the CB have a variety of fast axis azimuths that vary considerably. Along the Laramie array splits and nulls appear orthogonal to APM.

2.5.2 0 km Stack Plot

The 0 km stacks plot (Fig. 2.6) contains fewer splits with fast axis azimuths similar to APM. Most that are sub-parallel to APM are again south of the CB. Within the Lodore array, large δt splits, approaching 4 s are both sub-parallel and orthogonal to APM. The region south of the CB contains a variety of spatially mixed azimuthal trends from Steamboat Springs to the

southern terminus of the study area, and splits along the Laramie array are orthogonal to APM.

2.5.3 40 km Stack Plot

In the plot of the 40 km stacks (Fig. 2.7) new trends emerge as stacks along the Deep Probe array show fast axis azimuths from 10 - 25° from north. This azimuth range is shared with stations in the Laramie array. Stations in the CDROM array show fast axis azimuths approaching 40° from north both above and below the CB. The region south of Steamboat Springs contains a mix of azimuths similar to those seen in the 0 km stacks, but now intermingled with stations from the CREST array showing azimuths similar to those of the Deep Probe array.

2.5.4 100 km Stack Plot

The plot of 100 km stacks (Fig. 2.8) continues with the shift towards north seen in the 40 km stacks plot throughout the Lodore and Deep Probe arrays with azimuths in the 5 - 15° range. Azimuths for stations in the CREST and CDROM arrays range from 10 - 20° from north.

The trend among the three plots of stacked splits appears to be one of sinistral rotation of fast axis azimuths from the 0 km plot to the 100 km plot. Both the 0 km and 40 km plots show multiple trends of fast axis orientation in the region south of Steamboat Springs. Stations with azimuths sub-parallel to APM are more common south of the CB.

2.6 Discussion

Differences among the seismic stations represented on each plot have occurred due to high error values inherent in some of the stacks.

2.6.1 Unstacked Group(A) Plot

Below the CB, except for stations in the Laramie array, the fast axis orientation (FAO) for most of the data is consistent with APM. This indicates that for these stations the anisotropy detected might be due to flow in the upper mantle. Unfortunately, the APM trend is very similar to the strike of the CB and the Proterozoic subduction, so this data could also represent fossil trench parallel anisotropy from the Proterozoic. Split, and null split data along the Laramie array are possibly the result of fossil trench perpendicular anisotropy from the Proterozoic. The variety of FAO detected above the CB in the Rawlins region indicate complex anisotropy due to either lateral heterogeneity or possible detection of two layers of anisotropic material.

2.6.2 0 km Stack Plot

Results in the region where the CB is poorly defined, between the brown dashed lines, the complex anisotropy could indicate both trench parallel and trench perpendicular anisotropy. Or trench parallel and APM anisotropy. The detection of two trends of FAO south of Steamboat Springs that are not consistent with APM could indicate the imbrication of fossil anisotropy due to deformation affecting the upper mantle.

2.6.3 40 km Stack Plot

At this level of stacking, new trends in the data appear. Data following a new trend with FAO of 5 - 15° is mostly found in the lower elevations of the study area as indicated by the lighter topographical shading in figure 2.7. Anisotropy with this FAO is interpreted to be fossil anisotropy from the Proterozoic collision event that produced the Yavapai Province and the Cheyenne Belt Suture Zone. Detected anisotropy beneath the higher elevations appears sub-parallel to APM.

When overlaid on a map of Pn velocity perturbations varying from an average Pn velocity of 7.95 km/s [*Buehler and Shearer*, 2012], relationships appear (Fig. 2.9). The higher elevation locations with sub-parallel to APM FAO coincide with average to 3% below average velocity perturbations indicating higher lithospheric temperatures. Lower elevation locations with fossil Proterozoic anisotropic fabric coincide with average to 3% above average velocity perturbations correlating to cooler lithosphere.

The interpretation of this finding is that north trending (5° - 15°) FAO lithospheric fabric formed throughout the region during the Proterozoic suturing event. It remained preserved until the Farallon plate sank into the asthenosphere ~20 Ma (Fig. 2.10). This event allowed hot asthenosphere to heat the lithosphere, lifting the modern Rocky Mountains via buoyancy and thermal expansion. Increased temperature also caused the local erasure of the Proterozoic fossil anisotropy.

While the FAO beneath the mountainous regions of the study area could be due to later fossil anisotropy in the lithosphere, it is more likely the result of regional mantle flow.

2.6.4 100 km Stack Plot

At the largest radius of stacking in this study, the dominant data trend of an FAO 5 - 25° from north is consistent with many of the null-split data. This is possibly an expression of the Proterozoic subduction stress field, fossilized and detectable in the present. However, low δt values may indicate that the 100 km stacking radius surpassed the data's statistical usefulness.

2.7 Conclusions

The modified *Silver and Chan* [1991] method for characterization of upper mantle seismic anisotropy has proven effective in constraining seismic anisotropy in the Cheyenne Belt region.

A previously undetected regional fossil fabric of north trending fast axis orientations in the topographically lower areas of the study site are interpreted as anisotropic remnants of the Proterozoic stress field from the accretion of the Yavapai Province to the Wyoming Craton. Regions of FAO sub-parallel to APM in the mountainous areas is due to post Farallon plate heating of the lithosphere that locally erased the Proterozoic fossil anisotropy.

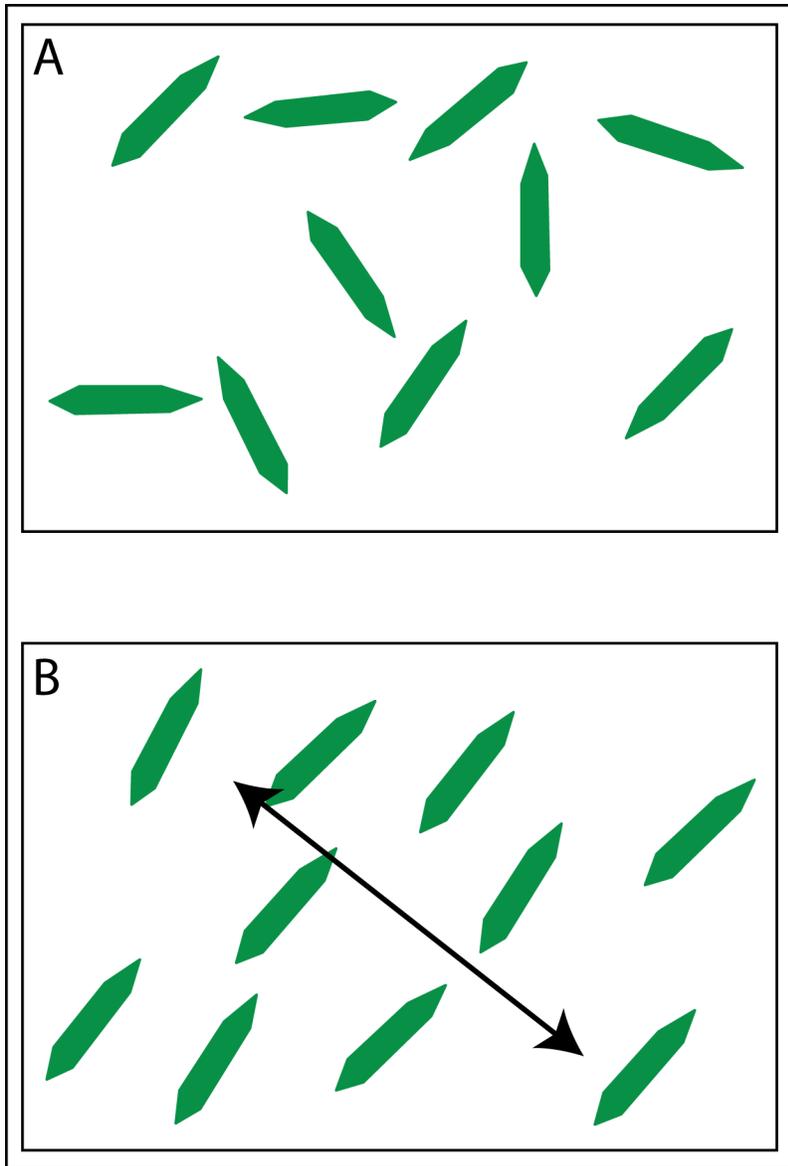

Figure 2.2. A depiction of the behavior of olivine crystals A. unstrained - no preferred orientation is observed; and B. strained - the crystalline structure of the olivine is altered via dislocation creep producing a lattice preferred orientation and anisotropy.
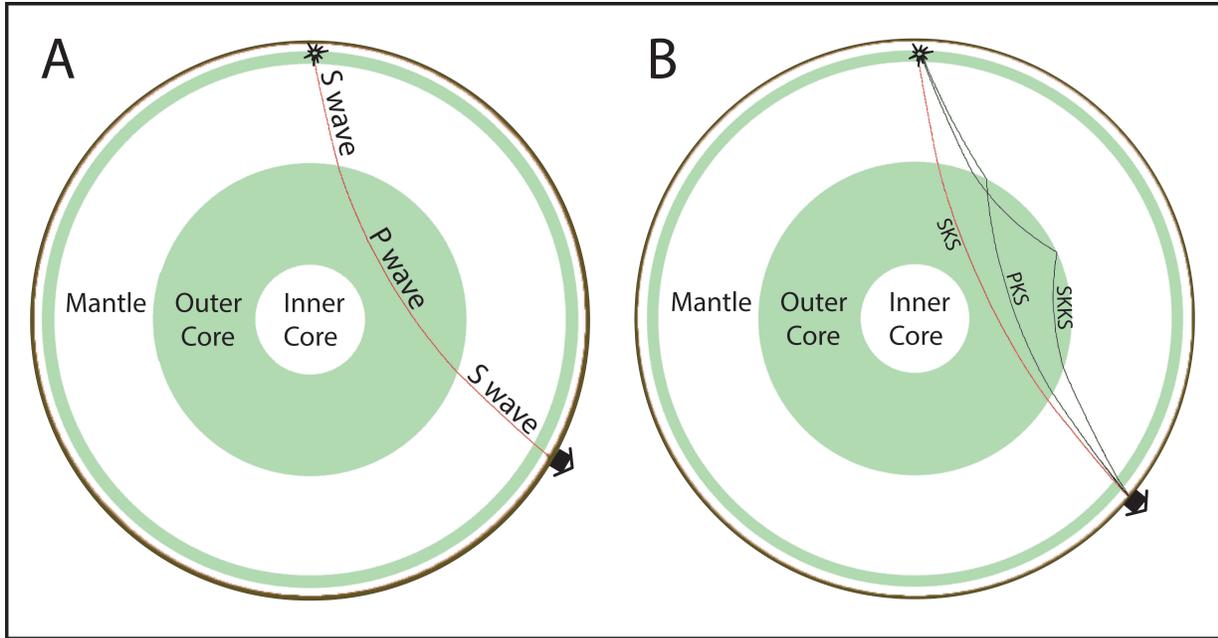

Figure 2.3. A. Depiction of an SKS wave. This wave begins as an S wave, but some of its energy is transferred to a P wave when it encounters the Earth's outer core. The outer core is liquid and does not support S wave particle motion. Any information about anisotropy the original S wave collected prior to its encounter with the outer core is lost when some of its energy becomes a P wave. When the P wave reaches the mantle, some of its energy becomes a new S wave. In this way, any anisotropy detected from an SKS wave is known to have occurred in the mantle between the outer core and the seismometer. B. Depiction of the phases used in this study: SKS, PKS, SKKS. After *Crotwell* [1999].
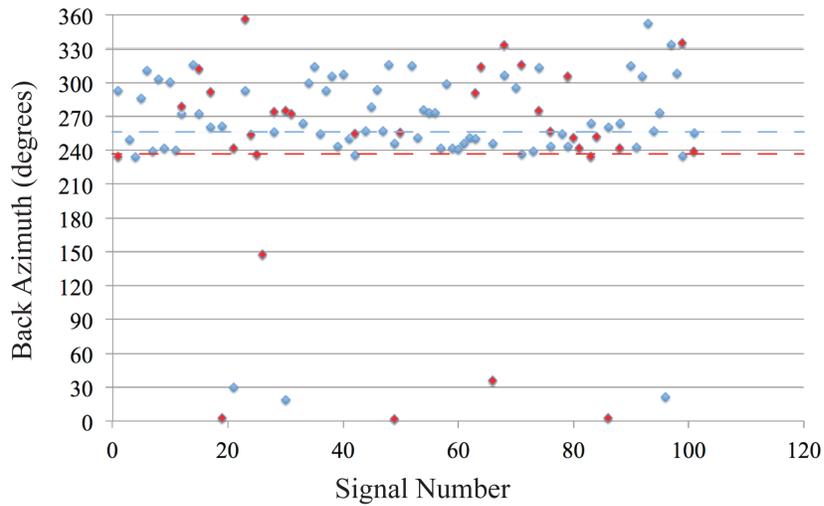

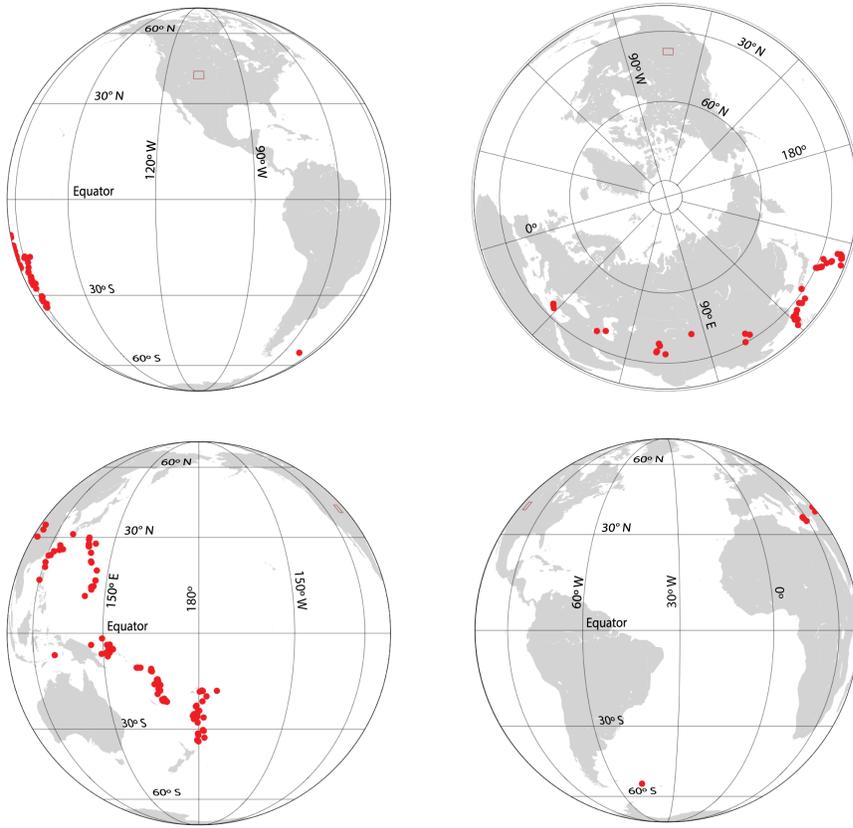

Figure 2.4. Upper for global projections depict the study site (red square) and earthquakes that provided data for the study. Lower plot shows back azimuth directions for Group(B) data in blue and Group(A) data in red. Blue and red dashed lines indicate the mean of Group(B) and Group(A) back azimuths respectively.

CHAPTER 3

This study has completed the majority of time-consuming research work in the form of

data acquisition and signal discrimination. The Group(B) signals are worthy of focus with a

multi-layer, complex anisotropy resolution technique such as that pioneered by *Menke and Levin*

[2003]. Potentially, the study area may produce results of two or more layers of anisotropy south

of the CB – fossil lithospheric fabric and APM. More interestingly, it may produce useful results

north of the CB where the possibility of two lithospheric fabrics – upper lithosphere and the

Cheyenne Slab – plus APM could be important to future seismic anisotropy studies.
